ABSTRACT

This report is prepared to have, in one document, a summary of all available data on the concentrations of radionuclides in samples of fish that were collected for our analysis from Bikini Atoll between 1977 and 1984. Some results have been presented in other published reports, and more detailed discussions of previously unpublished results are planned for future publications. Therefore, only a brief discussion of some results are provided herein. As found in other global studies, ¹³⁷Cs is most highly accumulated in edible flesh of all species of fish, the lowest fractions are found in the bone or liver. The mean concentration of $^{137}\mathrm{Cs}$ in muscle of reef fish from the southern part of the atoll is comparable to the global fallout concentration measured in market samples of fish collected from Chicago, Il., U.S.A., in 1982. ⁹⁰Sr is generally associated with non-edible parts of fish, such as bone or viscera. Twenty-five to fifty percent of the total body burden of ⁶⁰Co is accumulated in the muscle tissue; the remainder is distributed among the liver, skin, and viscera. The mean concentration of 60 Co in fish has been decreasing at a rate faster than radiological decay alone. Most striking is the range of ²⁰⁷Bi concentrations among different species of fish collected at the same time and place. Highest concentrations of ²⁰⁷Bi were consistently detected in the muscle (and other tissues) of goatfish and some of the pelagic lagoon fish. In other reef fish, such as mullet, surgeonfish, and parrotfish, 207 Bi was usually below detection limits by gamma spectrometry. Over 70 percent of the whole-body activity of $^{207}\mathrm{Bi}$ in goatfish is associated with the muscle tissue, whereas less than 5 percent is found in the muscle of mullet and surgeonfish. Neither ²³⁹⁺²⁴⁰Pu nor ²⁴¹Am is significantly accumulated in the muscle tissue of any species of fish. Apparently, $^{238}\mathrm{Pu}$ is in a more readily available form for accumulation by fishes than $^{239+240}\text{Pu}$. Based on a daily ingestion rate of 200 q of fish flesh, dose rates to individuals through the fish-food ingestion pathway are well below current Federal quidelines.

翦

INTRODUCTION

Bikini Atoll is located in the northern Marshall Islands at about $11^{\circ}36^{\circ}$ N, $165^{\circ}22^{\circ}$ E. The atoll now consists of 23 small coral islands surrounding a lagoon 35 km long, 21 km wide, and 630 km² in area. The average depth of the lagoon is 45 m. The total land area of the atoll is 6.2 km^2 . The Marshallese island names and the code letters and numbers we have assigned for reference to the islands of the atoll are shown in Table 1.

Bikini Atoll is one of two sites in the northern Marshall Islands used by the United States as testing grounds for nuclear devices from 1946 to 1958. The U.S. code names for the nuclear tests ¹ are shown in Table 2, and the approximate locations ^{2,3} of these tests are indicated in Fig. 1. The locations in Fig. 1 designated by the letter "k" are old disposal sites for island debris removed in the 1969 cleanup of Bikini and Eneu Islands ⁴. Most of the tests were detonated on barges anchored in the lagoon or on the reef. Two tests were air drops, two were underwater, and three were surface explosions. Different quantities of the radioactive fission and activation products, generated during the explosions, were deposited on the lagoon and on the islands of the atoll.

The U.S. moratorium on testing began on October 31, 1958, and marked the end of all nuclear testing at the atoll. However, even today quantities of long-lived fission products such as 137 Cs, 90 Sr, 155 Eu, and 113m Cd; activation products such as 55 Fe, 60 Co, and 207 Bi; and transuranium radionuclides such as 238,239,240,241 Pu and 241 Am persist in the atoll's environment. They are accumulated to different levels by indigenous terrestrial and aquatic plants and organisms that may be used as food by people.

In the marine environment, the contaminated lagoon sediments are the major source of man-made radionuclides for fish and other marine organisms. In 1977, we initiated detailed studies at Bikini Atoll to define the physical, chemical, and biological transport mechanisms and the fate of transuranic and other long-lived radionuclides in this environment. A variety of species of fish was collected for radionuclide analysis. One objective of our studies was to provide an updated assessment of radiological dose to individuals via the marine food pathway, fish being one of the major marine-food products in the Marshall Islands. this assessment were published in 1982. Our second objective was to evaluate the biological accumulation and behavior of the transuranium isotopes at the atoll. This task continued through 1985.

In conjunction with on-going studies at Enewetak Atoll, the collections and analyses of fish samples were conducted with several additional research objectives in mind. Among these objectives were studies to assess the differences in the concentrations of specific radionuclides in fish from different trophic levels, the magnitude of radionuclide concentration factors for different species of fish, the changes in body burdens of radionuclides in fish with time, tissue distributions of different radionuclides in different species of fish, the differences in radionuclide concentrations in fish from different regions of the atoll, and the usefulness of the current data for modeling concentrations of radionuclides accumulated by species of fish in similar or different marine environments.

The marine program at Bikini Atoll, supported by the Office of Health and Environmental Research of the Department of Energy, was phased out in 1985. Some of the results generated from this program have been discussed in published report $\$^{-10}$. However, there remain a great deal of data on radionuclide concentrations in fish that are not included in the documents referred to above. This report is prepared to have, in one document, all available data on the concentrations of radionuclides in samples of fish that we collected from Bikini Atoll between 1977 and 1984. This document and previously published reports $^{6-17}$ contains nearly all of the historical data on concentrations of radionuclides in fish from Bikini Atoll since the initiation of nuclear testing.

The radionuclides for which data are reported include all those detected by gamma spectrometry. In addition, the concentrations of $^{90}\mathrm{Sr}$, $^{113m}\mathrm{Cd}$, $^{238}\mathrm{Pu}$, $^{239+240}\mathrm{Pu}$, $^{241}\mathrm{Am}$, $^{210}\mathrm{Po}$, $^{210}\mathrm{Pb}$, and $^{210}\mathrm{Bi}$ are reported for those samples where radiochemical analysis was performed.

snapper), are hovering, midwater-to-surface carnivores. Another snapper, Letherinus kallopterus (pigfish), is a bottom dweller that feeds primarily on benthic crustacea. Jacks and snappers are in the fourth trophic level. Tuna, Euthunnus affinis (bonito) and Gymnosarda nuda (Dog Tooth Tuna), and mackerel, Grammatorcynus billineatus, are large, rapid-swimming carnivores that feed on small fish and any other prey of proper size. They represent species of the fifth trophic level. In the remainder of this report, common names rather than scientific names will be used for convenience.

SAMPLE PROCESSING AND ANALYSIS

Sample processing and analysis began with counting and partially thawing the fish from each location. The total weight, length, and sex of each fish was recorded. Each fish was dissected into muscle tissue, bone (cranial, thoracic, vertebrae, ribs, pelvic and pectoralgirdle), skin and scales (fins discarded), stomach (gizzard) contents, liver, and remaining viscera that generally included large and small intestines with contents, stomach wall, spleen, kidney, and mesenteries. The concentrations determined in the viscera samples are regrettably less descriptive than those for other tissues because of the matrix of organs and tissues represented. In some instances, however, a finer division of the visceral components was made. Each separate tissue and organ of the species from the same catch was pooled. It was necessary to pool tissues from a particular catch for analysis because of the low concentrations of transuranic radionuclides anticipated in edible muscle tissue. This resulted in the mixing of fish from several populations (weight classes) and of different sexes. Pecause mixing masked any differences in concentration related to weight (size), sorting of different size classes for processing was accomplished, in some instances, to assess the relationship of radionuclide concentration with weight. We were unable to relate any differences in concentrations of specific radionuclides with sex. Gills were separated from the fish but not analyzed. Our experience at Bikini and Enewetak Atolls showed that gills were frequently contaminated with sediment. Gills are not eaten and questionable information would be gained from their analysis because of the possible contamination.

After the wet weight was determined, each pooled fish tissue sample was dried in ovens at 90°C to constant dry weight and ashed in muffle furnaces at 450°C . The only samples not prepared in this way were the samples to be analyzed for ^{210}Po . In those cases, wet tissues and organs were used.

The scientific objectives for the analysis of fish in the Marshall Island program changed over the years. For example, initially fish were collected to assess the concentration of radionuclides in tissues of different species of fish. As the program progressed, dose assessment became an important issue, so our attention focused on the analysis of edible muscle tissue from fish collected at different locations. Later our interests shifted to evaluate the concentrations in muscle among different species collected simultaneously from the same lagoon location. As a result, not every tissue and organ separated from the fish collected over the years were processed for radionuclide analysis.

The mean dry/wet weight ratios for the tissues and organs most frequently analyzed are shown in Table 3. The dry/wet weight ratios of the stomach contents are of particular interest, because the differences noted attest to the different feeding habits of different species. The percentage that the organ or tissue was of the whole body fresh weight was also determined for several species. These values are given in Table 4.

The ashed samples were transferred to aluminum or plastic containers, sealed, and analyzed by gamma spectrometry at LLNL using a variety of Ge(Li)diode detector systems. Counting times were usually 1000 min or longer for each sample. A general purpose computer program, called GAMANAL, 19 was used for the data reduction of all gamma-ray spectra. In GAMANAL, the observed photopeak in the measured spectra is compared with a library of gamma-ray fission and activation products and naturally occurring radionuclides to identify the radionuclides in the sample. The program then applies correction factors for sample size, density, counting time, counting geometry, and decay to convert the measured counting rate to pCi/g of sample on the date of collection. The program also generates an upper-limit amount of specific spectral radionuclides based on those spectral regions where signals would be seen if the radionuclide were present in detectable quantities. Our minimal detectable concentrations (based on a counting time of 1000 min) for each of the longer-lived, man-made, gamma-emitting radionuclides routinely or occasionally detected in samples from the Marshall Islands are shown in Table 5.

After gamma analysis, a number of samples were selected for radiochemical analysis for 90 Sr, 137 Cs, 113m Cd, 238,239,240 Pu, 241 Am, 210 Po, 210 Pb, and 210 Bi. Activities of these radionuclides were measured using either alpha-

spectrometer systems or low-background beta detectors. Measurements of these radionuclides were conducted because some were judged to be of potential significance for dose assessments and others were analyzed to meet specific programmatic objectives. The ^{137}Cs was often radiochemically separated from muscle tissue and analyzed to confirm the measurements made by gamma spectrometry, which, in turn, provided a useful laboratory calibration for quality control.

Quality of data has always been an important aspect of our analytical measurements. As a standard practice, 5 to 10% of our time is devoted to quality-assurance work in all projects involving analytical measurements. This quality-assurance work includes:

- Analysis of background samples and blanks.
- Instrument calibration.
- Duplicate sampling and analysis.
- National and international interlaboratory standardization.
- Replicate measurements.
- Analysis and calibration traceable to National Bureau of Standards (NBS) samples.
- Appropriate statistical analysis of the results.

RESULTS AND DISCUSSION

Collection information, such as island sampled, common and scientific names of fish, number of fish pooled per sample, sex, average whole body weights, and average lengths, is presented in the odd-numbered tables in the Appendix. There is an odd-numbered table for each collection period. Each of these tables is followed by an even-numbered table showing the radionuclide concentrations in the separated tissues and organs from the species collected. The radionuclides detected most frequently in the muscle tissue and other organs by gamma spectrometry included (in addition to naturally occurring 40 K), 137 Cs, 60 Co, and 207 Bi. Occasionally the radionuclides 155 Eu, 241 Am, 125 Sb, 108 mAg, 102 mRh, and 113 mCd were also detected (by gamma spectrometry) in the viscera, liver, or stomach (gizzard) content samples of fish collected from the more contaminated regions of the atoll. The concentrations of the transuranics and other radionuclides in tissues and organs analyzed by wet chemical methods are also listed. The locations of the islands sampled (island locator letter and number) are shown in Fig. 1. All concentrations are listed relative to dry weight but the dry/wet weight ratios provided may be applied to convert concentrations to a wet-weight basis.

Representative whole fish concentrations of several radionuclides were reconstructed from the tissue and organ concentration data and the percentages of the respective tissues to whole body weight given in Table 4 for species representing 3 trophic levels (surgeonfish, mullet, trophic level II; goatfish, trophic level III; snapper, trophic level IV) collected from different islands of the atoll in 1978. These values were used to compute the percent of the whole body activity associated with the respective tissues. The results from these calculations are shown in Table 6 and are discussed in the following sections.

137_{Cs}

The results in Table 6 show that most 137 Cs accumulated by fish from the atoll is found associated with the edible flesh; the lowest fractions are associated with bone or liver. Concentrations of 137 Cs in the flesh of all four species are approximately equivalent to the concentration in the reconstructed whole body. There is no straightforward relationship between

a Muscle, skin, bone, liver, viscera and gizzard contents account for 93-98% of total fish weight. Data is from 1978 collections. Concentrations in gills, eyes, and reproduction organs were not determined.

•

 $[\]frac{b}{(\sum \frac{\text{pCi}}{\text{kg wet tissue}} \text{% tissue of whole body wt})} \sum_{\text{pCi}} \text{whole fish}$ $\sum \text{% tissue of whole body wt} \text{whole fish}$

the trophic position of the fish and their muscle burden of 137 Cs. The largest fraction of the 137 Cs is found in the muscle tissue of the 4th trophic level fish, snapper, and the lowest fraction in the 2nd trophic level fish, mullet. However, surgeonfish, also a 2nd trophic level species, have a larger fraction of the total 137 Cs in muscle tissue that is found in the 3rd trophic level fish, goatfish.

The data on the concentrations of 137 Cs in the muscle tissue of fish are presented here in several ways to help in the interpretation of results. Table 7 contains a summary of the mean and range of 137 Cs concentrations (no corrections were made for radioactive decay) in the muscle tissue of reef fish from different islands and of pelagic species from the laqoon during the 8-year period. Concentrations of 137 Cs in the muscle tissue of all species of fish during this period ranged from 7 to 460 pCi/kg wet wt. The maximum concentration of 137 Cs in flesh, 460 pCi/kg wet wt, was measured in surgeonfish collected from island B-1 in 1983 and the mean concentration in the flesh of all reef fish during the 8 year period was 113 pCi/kg wet wt.

The computed annual whole body dose equivalent rate to individuals from \$137_{Cs}\$ in the fish ingestion food pathway would have been less than 1 mrem. (Assuming a consumption rate of 200 g of fish flesh per day and a concentration of 113 pCi/kg wet wt).

Between 1977 and 1984, generally higher concentrations of 137 Cs were measured in muscle of reef fish from the northwest quadrant of the atoll (B-1 to B-5), and the lowest levels were found associated with reef species from the eastern reef of the atoll. In 1982, marine fish fillets purchased from stores in the Chicago area of the United States, contained 23±2 pCi/kg of 137 Cs derived from glabal fallout 20 . Table 7 shows that the mean concentrations of 137 Cs in fish from islands B-10 to B-23 is now comparable to the fallout levels in the store purchased fish.

Table 8 shows several examples of the different concentration for 137 Cs (pCi/kg wet wt) measured in the muscle tissue of different reef species collected from the same island during different years. The mean concentrations determined for all laqoon species during yearly intervals are shown in Table 7. There does not appear to be any precise trend indicating that the concentrations of 137 Cs in the muscle of these fish have been changing over the years at some consistent rate. There also appears to be no clear trends of consistent differences in concentrations among the different reef species simultaneously sampled from the same location (see Appendix). In 1978, for example, at island B-1, the highest concentration among the different reef

8/83	287		430	43				
9/84		53			16	13		

species was measured in mullet (Crenimugil). At Island B-1 in 1983 and at B-6 in 1980, the concentration in surgeonfish exceeded the measured concentration in mullet and goatfish. In 1984, the measured concentration of ¹³⁷Cs in the muscle tissue of goatfish was larger than the concentration measured in any of the pelagic species collected off the island; however, at B-6 and B-23 in 1978 and at B-6 in 1980, the concentration in goatfish was lower than the levels detected in pelagic species from the respective islands.

Unless there is some unforeseen impact on the lagoon, such as the disposal of uncontained, contaminated soil to the lagoon floor, there should be no significant change in the mean concentration of $^{137}\mathrm{Cs}$ in the flesh of fish collected from Bikini in the near future (other than a continuous reduction from radioactive decay). Any concentrations of $^{137}\mathrm{Cs}$ in the muscle tissue of fish caught at the atoll in future years should fall below the upper limit noted in the last 8 year period. Hence, future dose rates to individuals from $^{137}\mathrm{Cs}$ in the fish-food pathway may be predicted with a reasonable degree of certainty from a knowledge of the islands to be fished, the consumption rate of reef and pelagic fish, and parts of the fish normally eaten.

90_{Sr}

Concentrations of 90 Sr were measured in the tissues from a small subset of the fish, primarily from the collections made in 1978. Inspection of Table 6 shows that most of the 90 Sr accumulated by fish is, unlike 137 Cs, associated with non-edible parts such as bone and viscera. In surgeonfish, goatfish, and snapper, most of the body burden of 90 Sr is found in the bone tissue. In mullet, however, the viscera contains the major fraction of 90 Sr. The high concentration of 90 Sr in the viscera is probably due to 90 Sr associated with the bottom sediments, which are inqested with food and are present in the intestinal tract. Intestinal tract contents were not separated from the viscera sample.

Concentration of 90 Sr in the muscle tissue from all fish ranged from 0.2 to 5.7 pCi/kg wet wt. The mean concentration in muscle tissue is 1.7 pCi/kg wet wt. At this concentration and a consumption rate of 200 g of muscle tissue/d, the resulting mean dose-equivalent rate from 90 Sr in the marine fish-food ingestion pathway is less than 0.1 mrem/y. Concentrations of 90 Sr associated with muscle tissue are less than 3% of the concentration in the reconstructed whole fish (Table 6). Estimated dose-equivalent rates of 90 Sr from muscle only or from whole fish ingestion will differ by orders of magnitude. Therefore, it is misleading to use whole fish (or eviscerated whole fish) concentration data for 90 Sr to estimate radiological dose to individuals from 90 Sr in the marine fish-food pathway.

60_{Co}

Between 1958 (the end of nuclear testing at the atoll) and 1984, 60 Co levels in the atoll environment have decreased by a factor of 5 from radioactive decay alone ($t_{1/2}$ = 5.26 y). However, measurable concentrations of 60 Co are still found in fish and other aquatic organisms. In fish, 25-50% of the total body burden of 60 is present in the muscle tissue with most of the remainder distributed among the liver, skin, and viscera (see Table 6). The levels of 60 Co in the muscle tissue of reef fish from different regions in the atoll differ somewhat in the same way as that of 137 Cs except that fish from the southwest portion of the atoll contain concentrations comparable to those in fish caught in the northwest quadrant of the atoll. Concentrations of 60 Co in the muscle tissue of bottom-feeding mullet and qoatfish were consistently higher than levels in other reef species, such as surgeonfish and parrotfish, and in

pelagic species caught from the same island of the atoll. This pattern is repeated when concentrations in other tissues and organs of the different species are compared.

In Table 9 are shown mean concentrations in the muscle of reef and pelagic fish collected from the lagoon during different periods between 1977 and 1984. The mean concentration of 60 Co in the muscle tissue of fish has been decreasing at a rate faster than that from radiological decay alone. When appropriate data were found, a comparison was made between the concentrations in specific tissues and organs measured in the 1977-1984 collections to those detected in the same tissues of the species collected from the same locations during 1964 and 1969. 11,13 A least squares fit of the appropriate present and historical data shows that the mean level of 60 Co has been declining in the tissues of fish from Bikiniwith an effective decay constant of $0.22 + 0.05 \text{ y}^{-1}$ (effective half-life of 3.2 y). The effective decay constant is the sum of the physical decay constant (0.1317 y^{-1}) and an environmental loss rate term that reflects the removal rate of 60 Co. This removal rate is usually expressed as the ecological half-life (or decay constant) and has a value for 60 Co of 7.8 y. The disappearance of 60 Co from Bikini lagoon and its availability to fishes is controlled both by radiological decay and by processes of remobilization, transport, and dilution. If ⁶⁰Co continues to decline in the environment at the present rate, the mean concentration of $^{60}\mathrm{Co}$ in the edible muscle tissue of fish from the lagoon should be less than 20 pCi/kg wet wt by the year 1990.

Table 9. Mean concentrations of 60 Co in the muscle tissue of reef and pelagic fish collected at different times

	Collection		60Co (pCi/kg wet wt)		
	year intervals	Number of samples	Mean concentration	Range in concentrations	
All reef species	1977-1978	27	235±209	19-897	
	1980-1981	12	146±110	31-430	
	1982-1984	12	60±51	7-180	
All pelagic species	1977-1978	4	166±124	55-324	
	1981-1984	6	81±56	43-199	

The presence of 207 Bi ($t_{1/2} = 33.4 \text{ y}$) was first reported in marine samples obtained from the Pacific Proving Grounds in 1961. 21 It was formed possibly from a series of nuclear reactions such as 207 Pb(p,n) or 206 Pb(p,γ), assuming stable lead was present during testing as shielding material near the nuclear devices. 22 Other than a recent report describing 207 Bi as a component in global fallout debris 23 , it has not been detected elsewhere as a component of any waste discharged to aquatic environments from nuclear facilities.

Most striking was the range of concentrations found in tissues and organs among different species of fish collected at the same time and place (see Appendix). For three species of reef fish, mullet, surgeonfish, and parrotfish, ^{207}Bi in most parts of the fish was usually below detection limits by gamma spectrometry. However, the radionuclide was consistently detected in the muscle and other organs of goatfish and the pelagic lagoon Over 70 percent of the whole-body activity of ²⁰⁷Bi in goatfish and fish. pelagic fish is associated with the muscle tissue, whereas less than 5 percent (when detected) is found in the muscle of mullet and surgeonfish. Between 1977 and 1984, the concentrations in goatfish muscle ranged from a high of 1360 pCi/kg wet wt to a low of 17 pCi/kg wet wt, with the lowest levels found in fish collected from the eastern reef of the lagoon. There was no clear trend in the data to indicate that the concentration of $^{207}\mathrm{Bi}$ in the muscle of goatfish was changing with time at some constant rate. At B-1 and B-5, for example, the levels in muscle tissue were significantly less during the period of 1981-1983, compared to the concentrations measured in 1978. On the other hand, at B-6 and B-12, the concentrations measured in the muscle tissue of goatfish collected in 1984 were no different than the concentrations detected in 1978.

TRANSURANIUM RADIONUCLIDES

Several reports on the concentrations of the transuranium elements in Bikini fish have been published by this laboratory. 9,10,24 Only previously unpublished results and a few highlights from published data will be discussed in this report.

In Table 6 the data show that both $^{239+240}$ Pu and 241 Am are not significantly accumulated in the muscle tissue of any species of fish. Less than 1 percent of the total body burden of both $^{239+240}$ Pu and 241 Am is associated with the muscle tissue of all reef species. Somewhat higher fractions, but lower concentrations, were found associated with muscle tissue of pelagic species. The distributions of $^{239+240}$ Pu and 241 Am among the other tissues of the reef and pelagic species are also different. For example, the bone and skin of reef fish contain much less of the total body burden than that of snapper. These differences appear to be independent of location and the level of contamination and much more dependent on species.

Arithmetic mean concentrations of ²³⁹⁺²⁴⁰Pu, ²³⁸Pu, and ²⁴¹Am in edible muscle tissue from all fish collected at Bikini during different periods between 1977 and 1984 are shown in Table 10. The results also show that there has been essentially no change in the mean concentration of ²³⁸⁺²⁴⁰Pu during the years of collection. Mean concentrations of the transuranic radionuclides in the flesh of fish from Bikini Atoll are a fraction of a pCi/kg wet wt. Barring any major impact on the lagoon environment that might affect the availability of the transuranic radionuclides to marine organisms, mean concentrations in the flesh of fish collected over the next 10 to 20 years should not differ greatly from present day values. The 30-y committed-dose equivalent to the bone marrow of individuals from the transuranic radionuclides in the fish-flesh-ingestion pathway (using 200 g/d as the ingestion rate and the mean value for flesh concentration) ranges from 3 to 6 mrem. This range results from increasing the adult gut-transfer coefficient for plutonium 9 from 1 x 10^{-4} to 5×10^{-4} . In fish with relatively high body burdens of $^{239+240}$ Pu, the $^{238}\mathrm{Pu}$ to $^{239+240}\mathrm{Pu}$ activity ratio in the muscle and other internal organs was usually higher than the activity ratio found in the material ingested by the fish. In many cases, the error associated with the measurements of ²³⁸Pu was large, and it could be argued that the differences among the samples were not real. However, the patterns repeat themselves regardless of the error associated with counting, indicating that the trends found for the different ratios among the tissues and gut-content samples of the fish are real. This indicates the possibility of discrimination between isotopes of plutonium, which is difficult to accept from a purely chemical viewpoint.

Table 10. Summary of transuranic concentrations in the flesh of all fish from Bikini Atoll.

			pCi/kg wet wt ^a				
	Period	239+240 _{Pu}	238 _{Pu}	241 _{Am}			
Arithmetic mean	1977-1978 1977-1981 1977-1984	0.39±0.34 0.37±0.32 0.29±0.30	0.020±0.021	0.18±0.28

a If the radionuclide was below limits of detection, the concentration is not included in the average.

steps were taken to analyze if discrimation between the isotopes of plutonium was taking place. Gizzard and intestinal contents were removed from samples of mullet collected from the more contaminated regions of Bikini and equilibrated with seawater for 5 hours. (Five hours is usually the normal time for the ingested material to pass through the gut of mullet.) From this experiment, the $^{238}\text{Pu}:^{239+240}\text{Pu}$ activity ratio was determined in the solid phase and in solution. Five sets of results are shown in Table 11. In every case, more ^{238}Pu relative to $^{239+240}\text{Pu}$ is measured in solution, which indicates that $^{238}\text{Pu}:$ in the material ingested by fish must be in a more readily soluble form than $^{239+240}\text{Pu}$.

The concentrations of $^{239+240}$ Pu and 241 Am in fish from the lagoon differ markedly from organ to organ and species to species. Less than 20 percent of the samples showed the same relative amounts of 241 Am and $^{239+240}$ Pu in the body parts analyzed. Concentrations of plutonium in most fish parts from any location collected during different years have comparable concentrations showing that the fish maintain restricted feeding territories. The concentration ratio of 241 Am to $^{239+240}$ Pu in muscle, bone, skin, or liver was always either equivalent to or less than the ratio in the gut

contents or viscera. If the internal body burdens of transuranic nuclides are accumulated by the fish through the qut, then it could be concluded that in most cases there is a discrimination against 241 Am relative to $^{239+240}$ Pu in different tissues.

Table 11. Activity ratios of 238 Pu: $^{239+240}$ Pu in liquid and solid phases of gut contents after equilibration with seawater.

Solid phase	Liquid phase	Solid:liquid phase
0.0081	0.13	0.062
0.048	0.11	0.43
0.003	0.14	0.021
0.010	0.22	0.045
0.0034	0.27	0.13

Curium-242,243,244 have been detected in some fish tissues from Bikini. Concentrations of 243 , 244 Cm are a few percent of the $^{239+240}$ Pu concentrations and 242 Cm is less than 1 percent of the $^{239+240}$ Pu levels in the entire fish. The detection of 242 Cm ($t_{1/2}$ = 163 d), approximately 25 years after the end of testing, indicates the presence of a parent radionuclide, 242 Mm, in the environment.

OTHER RADIONUCLIDES

Concentrations of 113m Cd and naturally occurring 210 Pu, 210 Po, and 210 Bi determined in fish samples are listed in the Appendix. Discussions of the concentrations and significance of these radionuclides at Bikini Atoll have been presented in the literature 6,7,8 and will not be repeated here.

SUMMARY

Over 1550 fish representing species from all trophic levels were collected from regions of Bikini lagoon between 1977 and 1984. Concentrations of gamma-emitting radionuclides accumulated in the different tissues and organs of these fish were determined. A number of samples were selected for the radiochemical analysis of $^{90}\mathrm{Sr}$, $^{113m}\mathrm{Cd}$, $^{238},^{239},^{240}\mathrm{Pu}$, $^{241}\mathrm{Am}$, $^{210}\mathrm{Po}$, $^{210}\mathrm{Pb}$, and $^{210}\mathrm{Bi}$. Activities of these radionuclides were measured in the tissues using appropriate alpha-spectrometer systems or low-background beta detectors. All the radionuclide-concentration data are tabulated in the Appendix.

A reasonable data base was developed over the 8-year period to define adequately the range in concentrations of the different radionuclides in edible muscle tissue and other organs of fish from the lagoon at Bikini Atoll. Unless there is some unforeseen impact on the lagoon that would significantly alter the environmental concentrations of the different radionuclides, there is little reason to expect that concentrations of the different radionuclides in fish in future years will exceed the upper concentration limits determined over the last 8-year period. The present mean levels of radionuclides in edible muscle tissue of fish can be used with a reasonable degree of confidence to predict the magnitude of future radiological doses to individuals from the marine fish-food pathway at Bikini Atoll.

ACKNOWLEDGMENTS

The collection and publication of the data in this report was made possible through the efforts of a group of people too numerous to list. They include the crew on the research vessels, Liktanur I and II, and a number of individuals associated with Lawrence Livermore National Laboratory who assisted in the field collections and sample processing. This work was performed under the auspices of the U.S. Department of Energy under contract number W-7405-Eng-48.
